Decision trees

UCSD Medical Center (1970s): identify patients at risk of dying within 30 days after heart attack.

Decision trees

UCSD Medical Center (1970s): identify patients at risk of dying within 30 days after heart attack.

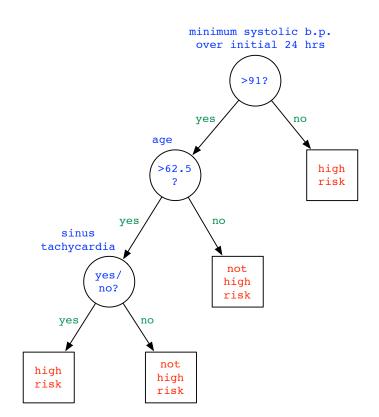

Data set: 215 patients. 37 (=20%) died. 19 features.

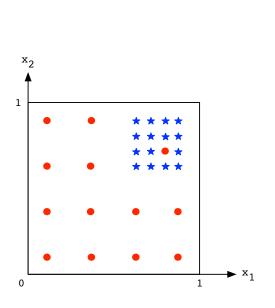

Decision trees

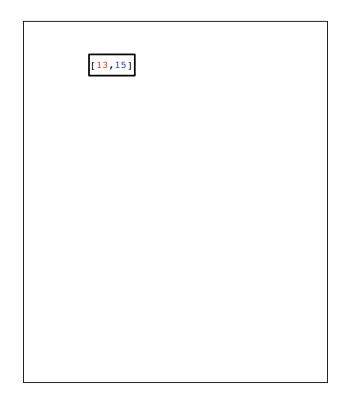

UCSD Medical Center (1970s): identify patients at risk of dying within 30 days after heart attack.

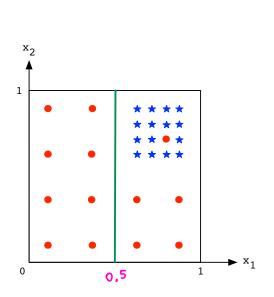

Data set: 215 patients. 37 (=20%) died. 19 features.

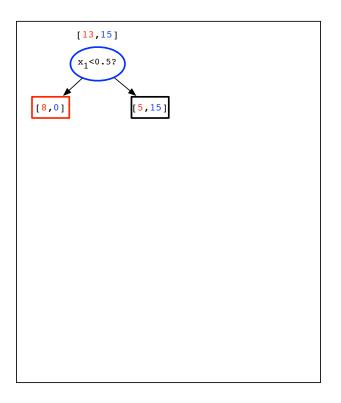

interpretable

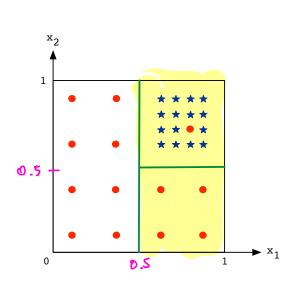

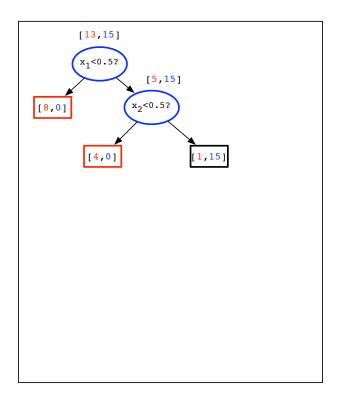

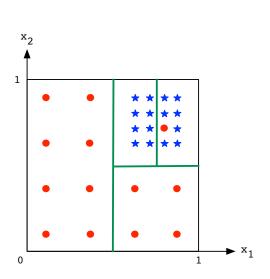

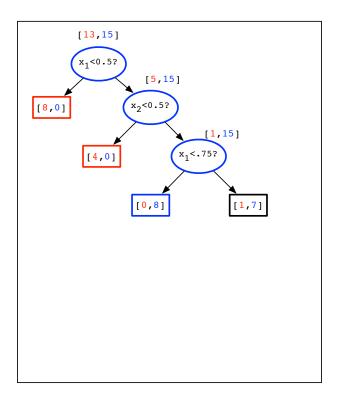

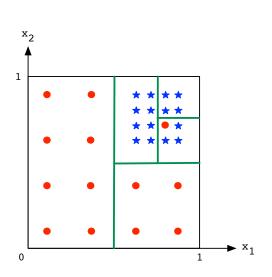

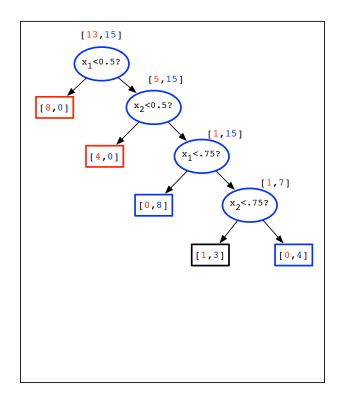

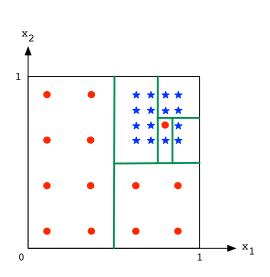

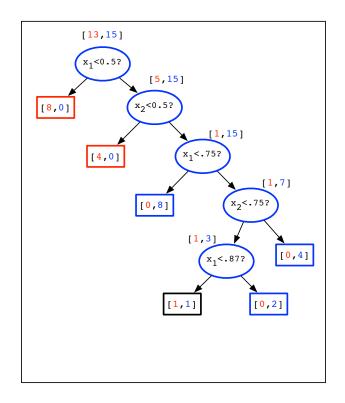

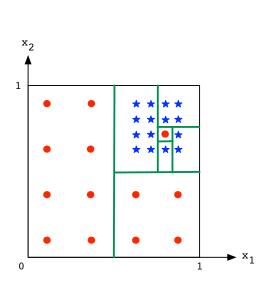

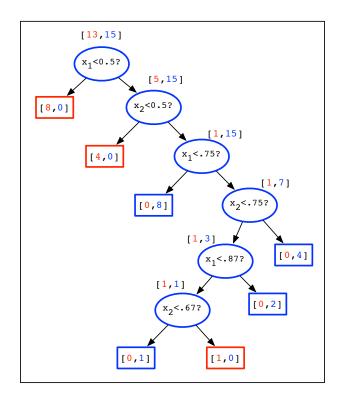

Greedy algorithm: build tree top-down.

- Start with a single node containing all data points
- Repeat:
 - Look at all current leaves and all possible splits
 - Choose the split that most decreases the uncertainty in prediction

We need a measure of uncertainty in prediction.

Uncertainty in prediction

Say there are two labels:

```
+ label p fraction of the points
- label (1-p) fraction of the points
```

What uncertainty score should we give to this?

Uncertainty in prediction

Say there are two labels:

$$p(1-p) + (1-p) p$$

$$+$$
 label p fraction of the points $-$ label $(1-p)$ fraction of the points

What uncertainty score should we give to this?

Misclassification rate

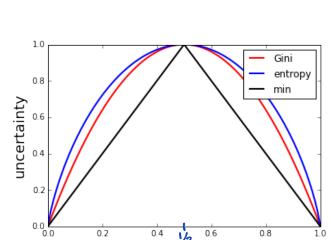

$$\min\{p, 1-p\}$$

Gini index

$$\rightarrow$$
 $2p(1-p)$

3 Entropy

$$p\log\frac{1}{p}+(1-p)\log\frac{1}{1-p}$$

0.4

0.2

p = 1/2: highest uncertainty p = 0 or 1: lowest uncertainty

0.8

1.0

Uncertainty: *k* **classes**

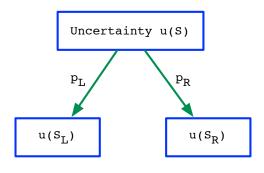

Suppose there are k classes, with probabilities p_1, p_2, \ldots, p_k .

	k = 2	General k
Misclassification rate	$min\{oldsymbol{p}, 1-oldsymbol{p}\}$	$1-\max_i p_i = 1-\ p\ _\infty$
Gini index	2p(1-p)	$\sum_{i eq j} p_i p_j = 1 - \ p\ ^2$
Entropy	$p\log\frac{1}{p} + (1-p)\log\frac{1}{1-p}$	$\sum_{i} p_{i} \log \frac{1}{p_{i}}$

Benefit of a split

Let u(S) be the uncertainty score for a set of labeled points S.

Consider a particular split:

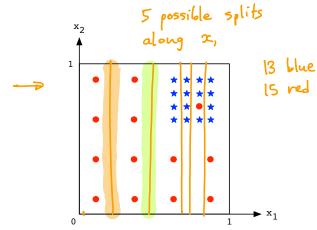

Of the points in *S*:

- p_L fraction go to S_L
- p_R fraction go to S_R

Benefit of split = reduction in uncertainty:

$$\left(u(S) - \underbrace{(p_L \, u(S_L) + p_R \, u(S_R))}_{\text{expected uncertainty after split}}\right) \times |S|$$

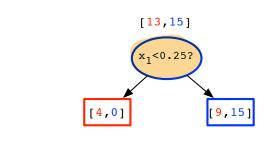

Benefit of a split: example

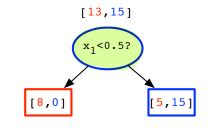

Initial Gini uncertainty:

$$2\times\frac{13}{28}\times\frac{15}{28}$$

d features, n data points =) at most d(n-1)

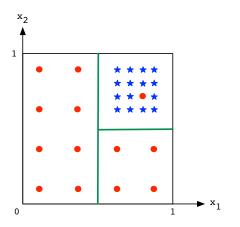

$$p_L u_L + p_R u_R = \frac{4}{28} \cdot 0 + \frac{24}{28} \cdot 2 \cdot \frac{9}{24} \cdot \frac{15}{24} = \frac{45}{112}$$

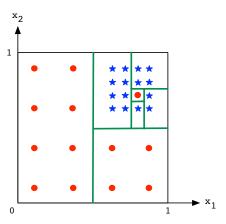

$$p_L u_L + p_R u_R = \frac{8}{28} \cdot 0 + \frac{20}{28} \cdot 2 \cdot \frac{5}{20} \cdot \frac{15}{20} = \frac{30}{112}$$

Overfitting?

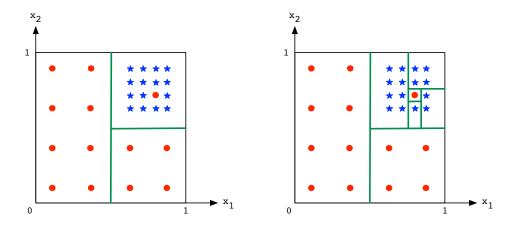

Go back a few steps...

Overfitting?

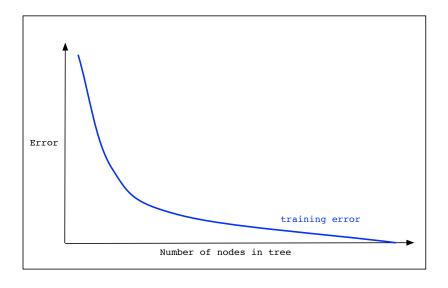

Go back a few steps...

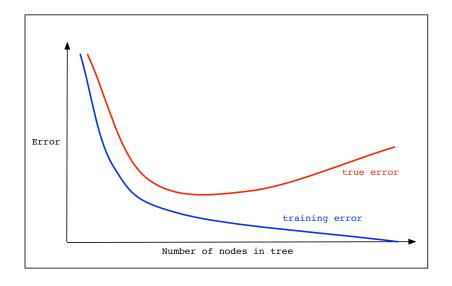

Final partition does better on training data, but is more complex. That one point might have been an outlier anyway.

We have probably ended up **overfitting** the data.

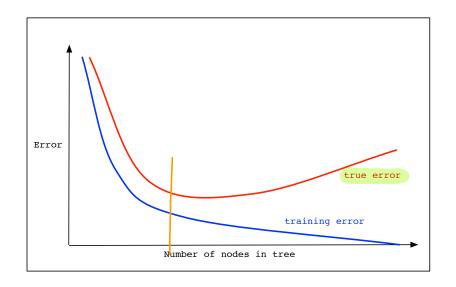

Overfitting: picture

Overfitting: picture

Overfitting: picture

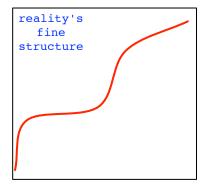

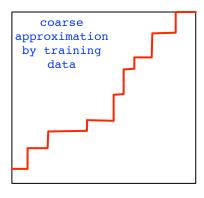

As we make our tree more and more complicated:

- training error keeps going down
- but, at some point, true error starts increasing!

Overfitting: perspectives

- The true underlying distribution *D* is the one whose structure we would like to capture.
- The training data reflects the structure of D, so it helps us.
- But it also has chance structure of its own we must avoid modeling this.

Decision tree issues

A very expressive family of classifiers:

- Can accommodate any type of data: real, Boolean, categorical, ...
- Can accommodate any number of classes
- Can fit any data set
- Statistically consistent

Decision tree issues

A very expressive family of classifiers:

- Can accommodate any type of data: real, Boolean, categorical, ...
- Can accommodate any number of classes
- Can fit any data set
- Statistically consistent

But this also means that there is serious danger of overfitting.

- Start with a single node containing all data points
- Repeat:
 - Look at all current leaves and all possible splits
 - Choose the split with the greatest benefit

When to stop?

- Start with a single node containing all data points
- Repeat:
 - Look at all current leaves and all possible splits
 - Choose the split with the greatest benefit

When to stop?

- When each leaf is pure?
- When the tree is already pretty big?
- When each leaf has uncertainty below some threshold?

- Start with a single node containing all data points
- Repeat:
 - Look at all current leaves and all possible splits
 - Choose the split with the greatest benefit

pruning Policy P

When to stop?

- When each leaf is pure?
- When the tree is already pretty big?
- When each leaf has uncertainty below some threshold?

Common strategy: keep going until leaves are pure.

Then, shorten the tree by **pruning**, to correct for overfitting.

e.g.
with a validation
set
